画 🔺 👘 亜

DQC

The Midterm is next week Tuesday, August 13.

- Approximately 50 multiple choice questions.
- You do not need a scantron.
- Questions will be mostly conceptual.
- You may bring any basic or graphing calculator.
- I will bring extra scratch paper.

Sac

<ロト (四) (三) (三) (三) (三)

- Write an exam question that would be appropriate for your midterm.
- The midterm will cover material from Chapters 1, 2, and 3.
- Your exam question must come from material covered in class, your homeworks, or your labs.
- Questions may be either multiple choice or short answer.
- To receive any credit, you must write an original question and provide both the question and the correct answer.

These can be submitted on iLearn (Assignments tab). It opens today at 9:30am and will close on Thursday at 11:59pm.

5900

- Independence of random processes is similar to independence of variables and observations.
- We say that two random processes are **independent** if knowing the outcome of one provides no useful information about the outcome of the other.

・ロト ・回ト ・ヨト ・

포 문 표

San

For example, consider our discussion on rolling 2 six-sided dice.

- The roll of the first die has no effect on the roll of the second die.
- Thus our two dice rolls are independent of one another.

Sar

《日》 《圖》 《문》 《문》 [] 문)

We've already calculated the probability of the two rolls both being a 1

- 1/6 of the time the first roll is a 1
- A further 1/6 of *those* times the second is also a **1**.
- So we decided that the probability was $(1/6) \times (1/6) = 1/36$. Multiplying these probabilities together works because the two events are independent.

Let A and B be events from two different and independent processes. Then the probability that both A and B occur can be calculated as the product of their separate probabilities:

$$P(A \text{ and } B) = P(A) \times P(B)$$

Similarly, if there are k events A_1, \ldots, A_k from k independent processes, then the probability they all occur is

$$P(A_1) \times P(A_2) \times \cdots \times P(A_k)$$

Sar

About 9% of people are left-handed. Suppose 2 people are selected at random from the U.S. population. Because the sample size of 2 is very small relative to the population, it is reasonable to assume these two people are independent.

- What is the probability that both are left-handed?
- **②** What is the probability that both are right-handed?

What is the probability that both are left-handed?

- Let L_1 be the event that the first person is left-handed and L_2 the event that the second person is left-handed.
- We are told that 9% of people are left-handed, so $P(L_1) = P(L_2) = 0.09.$

What is the probability that both are left-handed?

• We are assuming that these people are independent, so we can use the multiplication rule:

$$P(L_1 \text{ and } L_2) = P(L_1) \times P(L_2)$$

= (0.09) × (0.09)
= 0.0081

or 0.81% (this is highly unlikely!)

200

<ロト (四) (三) (三) (三) (三)

What is the probability that both are right-handed?

- First, assume that everyone is either right- or left-handed.
- Then L_1^c is the event that the first person is right-handed and L_2^c is the event that the second person is right-handed.
- From the previous slide, we decided that $P(L_1) = P(L_2) = 0.09$
- So $P(L_1^c) = 1 P(L_1) = 1 0.09 = 0.91$ and $P(L_2^c) = 0.91$

What is the probability that both are right-handed?

• We are still assuming that these people are independent, so we can again use the multiplication rule:

$$P(L_1^c \text{ and } L_2^c) = P(L_1^c) \times P(L_2^c)$$

= (0.91) × (0.91)
= 0.8281

or 82.81%.

200

<ロト (四) (三) (三) (三) (三)

If two events are disjoint, are they independent?

Section 3.1

If two events are disjoint, are they independent?

- Recall that independent events have no relationship with one another.
- This means that if we know something about event A, we don't get any information about event B.
- For disjoint events, if event A occurs, we can be totally certain that event B did not occur.
- Therefore they are *dependent*.

- 12

Sar

(日) (四) (日) (日)

Consider two disjoint events for rolling a six-sided die. Let $A = \{1\}$ be the event that I roll a 1 and $B = \{2\}$ the event that I roll a 2.

- If I know that A occurred, then I can be 100% sure that B did not occur.
- If I know that A did not occur, then I know that the roll must be a 2, 3, 4, 5, or 6.
 - Now there are five possible options instead of six!
 - We've narrowed down our options, so knowing that I did not roll a 1 has given us some useful information.

Therefore A and B can't be independent.

We can get far more information out of the relationships between multiple variables than we can from a single variable. For example

- Recall our case study on the malaria vaccine.
- We can look at P(infection), but that doesn't tell us anything about the efficacy of the vaccine.
- Instead, we want to look at the probability that a person develops infection *if they were vaccinated*.
- We compare this to the probability that a person develops infection if they were not vaccinated.

Sar

<ロト (四) (三) (三) (三) (三)

Let's consider a data set on a machine learning classifier.

- The classifier is designed to take images and determine whether each one is about fashion.
- The classifier groups 1822 photos into either "fashion" or "not fashion".
- Separately, these photos are grouped into "fashion" and "not fashion" by a group of people.
 - We take these groupings as the truth that the classifier is trying to get at.

We can take these groupings and build them into a contingency table.

		trut		
		Fashion	Not	Total
classifier	Fashion	197	22	219
classifier	Not	112	1491	1603
	Total	309	1513	1822

We think about this a lot with classification problems!

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822

- When we build our classifier, we want to know the rate at which it correctly and incorrectly identifies fashion and not fashion.
- This will give us an idea of how successful our classifier is.
 - Is it a good classifier?
 - Should we try a different machine learning algorithm?

19 / 79

- If the photo is actually about fashion, what is the probability that the classifier correctly identified it as being about fashion?
- If the classifier predicted that a photo was not about fashion, what is the probability that it was incorrect?

20 / 79

• □ ▶ • □ ▶ • □ ▶ •

5900

Example: Contingency Table Probabilities

If the photo is actually about fashion, what is the probability that the classifier correctly identified it as being about fashion?

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
classifier	pred not	112	1491	1603
	Total	309	1513	1822

- We know that the photo is actually about fashion, so we focus our attention to the column where truth is fashion.
- Then within this column, we look for the number of times the classifier pred fashion out of the total number of fashion photos.

If the photo is actually about fashion, what is the probability that the classifier correctly identified it as being about fashion?

		1		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822

 $P(\text{classifier is pred fashion } given \text{ truth is fashion}) = \frac{197}{309}$

or 0.638, a reasonable correct identification rate for fashion.

If the classifier predicted that a photo was not about fashion, what is the probability that it was incorrect?

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822

• We know that classifier is pred not fashion, so we focus our attention to this row.

• We want to know the probability that it was incorrect, or in truth is fashion.

San

If the classifier predicted that a photo was not about fashion, what is the probability that it was incorrect?

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822
				119

 $P(\text{truth is fashion } given \text{ classifier is pred not}) = \frac{112}{1603}$

or 0.070, a low misidentification rate for fashion photos.

・ロット 4回ッ 4回ッ 4回ッ 4日>

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822

- We've now used our contingency table to think about two types of probabilities.
 - The probability for a single event (from the row and column of totals).
 - The probability for multiple events together (from the numbers in the middle).

- A marginal probability is a probability based on a single variable.
- Think of the *margins* as the edges of a contingency table where we have the information for each variable individually.

26 / 79

イロト イヨト イヨト イ

≡▶ ≡ ∽੧<

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822

A probability based solely on our **classifier** is a marginal probability. It is based on a single variable without regard to any other variables.

```
P(\text{classifier is pred fashion}) = 219/1822
```

200

- A **joint probability** is a probability for two or more variables together.
- Think of this as a probability that two or more variables occur *jointly* (together).

		truth		
		fashion	not fashion	Total
classifier	pred fashion	197	22	219
	pred not	112	1491	1603
	Total	309	1513	1822

The probability that our classifier is pred fashion and the truth is fashion is a joint probability. It is based on two variables together.

P(classifier is pred fashion and truth is fashion) = 197/1822

We can examine marginal and joint probabilities using table proportions. **Table proportions** are computed by dividing each count in a contingency table by the table's grand total.

		truth		
		fashion	not fashion	Total
classifier	pred fashion	0.108	0.012	0.120
	pred not	0.062	0.818	0.880
	Total	0.170	0.830	1.000

4 ロ ト 4 回 ト 4 三 ト 4 三 ト 三 つ Q (* 30 / 79

A joint probability distribution is just a probability distribution for multiple variables together.

Joint Outcome	Probability
classifier is pred fashion and truth is fashion	0.108
classifier is pred fashion and truth is not fashion	0.012
classifier is pred not and truth is fashion	0.062
classifier is pred not and truth is not fashion	0.818
Total	1.000

Note: A marginal probability distribution is the type of probability distribution we introduced last week!

3

San

・ロト ・回ト ・ヨト ・

Marginal and Joint Probabilities

We can compute marginal probabilities using joint probabilities.

Joint Outcome	Probability
classifier is pred fashion and truth is fashion	0.108
classifier is pred fashion and truth is not fashion	0.012
classifier is pred not and truth is fashion	0.062
classifier is pred not and truth is not fashion	0.818
Total	1.000

For example,

$$\begin{split} P(\texttt{truth is fashion}) &= P(\texttt{classifier is pred fashion and truth is fashion}) \\ &+ P(\texttt{classifier is pred not and truth is fashion}) \\ &= 0.108 + 0.062 \\ &= 0.170 \end{split}$$

<□ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > <

This makes sense based on our table proportions!

		truth		
		fashion	not fashion	Total
classifier	pred fashion	0.108	0.012	0.120
	pred not	0.062	0.818	0.880
	Total	0.170	0.830	1.000

- All of these numbers are directly proportional to our original contingency table.
- The row and column of totals represent the marginal probabilities.
- These totals are the actual sums of their respective rows/columns.

3

Sar

- The classifier predicts whether a photo is about fashion, but it is not perfect.
- We'd like to know how we can use these predictions to improve our understanding of the second variable, the truth.
- We might want to know, for example, the probability that the truth is fashion given that the classifier predicts fashion.

The probability that a random photo from the data set is actually about fashion is 0.17. Suppose we know that classifier is pred fashion.

- Now we can get a better estimate of the probability that the truth is fashion.
- We do this by restricting our attention to the 219 cases where the classifier is pred fashion.
- Then we look at the fraction of *these* photos where the truth is fashion (197 cases).

 $P(\text{truth is fashion given classifier is pred fashion}) = \frac{197}{219}$

- When we are given some useful information that allows us to restrict our attention, we call these probabilities **conditional probabilities**.
- We can say that we condition based on some *given* information, or that we computed the probability under the *condition* that the classifier is pred fashion.

There are two important aspects to a conditional probability:

- The **outcome of interest** is whatever we want to know about.
- The condition is information we know to be true, a known outcome or event.

(日) (四) (日) (日)

3

We separate our outcome of interest from our condition in our probability notation with a vertical bar:

P(truth is fashion given classifier is pred fashion)

becomes

 $P(\text{truth is fashion} \mid \text{classifier is pred fashion}) = \frac{197}{219}$

We read the vertical bar as the word given.

Earlier, we computed

P(truth is fashion given classifier is pred fashion) = 0.900

by restricting our attention to the data where classifier is pred fashion.

From this row where classifier is pred fashion, we took the number of cases where truth is fashion and divided by the row total to get our answer.

However, we don't always have access to the count data. Instead we are given only the probabilities.

	truth		
	fashion	not fashion	Total
pred fashion	0.108	0.012	0.120
pred not	0.062	0.818	0.880
Total	0.170	0.830	1.000
-	pred not	fashionpred fashion0.108pred not0.062	fashionnot fashionpred fashion0.1080.012pred not0.0620.818

500

- Suppose we took a sample of 1000 photos.
- We could multiply each probability by 1000 to get an estimate of how many would fall into each place in our contingency table.
- We would anticipate $0.120 \times 1000 = 120$ to be the number of cases where classifier is pred fashion.
- We would expect to see $0.108 \times 1000 = 108$ cases where truth is fashion and classifier is pred fashion

- 12

5900

(日) (四) (日) (日)

We can use these numbers to compute our conditional probability. (Using our count data, we found 197/219 = 0.90.)

 $P(\text{truth is fashion given classifier is pred fashion}) = \frac{\# \text{ cases (truth is fashion and classifier is pred fashion)}}{\# \text{ cases (classifier is pred fashion)}} = \frac{108}{120} = \frac{0.108 \times 1000}{0.120 \times 1000} = \frac{0.108}{0.120} = 0.90$

This is the ratio, or fraction, or two probabilities. We can rewrite this as

$$\begin{split} P(\texttt{truth is fashion given classifier is pred fashion}) \\ &= \frac{P(\texttt{truth is fashion and classifier is pred fashion})}{P(\texttt{classifier is pred fashion})} \\ &= \frac{0.108}{0.120} = 0.90 \end{split}$$

This leads us to the general **conditional probability formula**:

Let A and B be outcomes. The conditional probability of outcome A occurring given the condition that B has occurred is

$$P(A|B) = \frac{P(A \text{ and } B)}{P(B)}$$

Section 3.2

Find the probability that the classifier is incorrect when classifying a photo about fashion.

Find the probability that the classifier is incorrect when classifying a photo about fashion.

- We know that the photo is about fashion.
 - We can write that truth is fashion.
 - This information is given, or our condition.
- From that, we want to know the probability that the classifier is wrong.
 - We want to know the probability that the classifier results in not fashion.

Sar

<ロト (四) (三) (三) (三) (三)

Find the probability that the classifier is incorrect when classifying a photo about fashion.

Putting this all together, we want

 $P(\text{classifier is not fashion} \mid \text{truth is fashion})$

Using our formula

$$P(A|B) = \frac{P(A \text{ and } B)}{P(B)}$$

we let A be the event that classifier is not fashion and B the event that truth is fashion. Then

$$\begin{split} P(\texttt{classifier is not fashion} \mid \texttt{truth is fashion}) \\ = \frac{P(\texttt{classifier is not fashion and truth is fashion})}{P(\texttt{truth is fashion})} \end{split}$$

		truth		
		fashion	not fashion	Total
classifier	pred fashion	0.108	0.012	0.120
	pred not	0.062	0.818	0.880
	Total	0.170	0.830	1.000

$$\begin{split} P(\texttt{classifier is not fashion} \mid \texttt{truth is fashion}) \\ &= \frac{P(\texttt{classifier is not fashion and truth is fashion})}{P(\texttt{truth is fashion})} \\ &= \frac{0.062}{0.170} = 0.363 \end{split}$$

Section 3.2

The smallpox data set is a sample of 6224 individuals from the year 1721.

		inoculated		
		yes	no	Total
result	lived	238	5136	5374
	died	6	844	850
	Total	244	5980	6224
	-			

<□▶ <□▶ <三▶ <三▶ <三▶ 三 のQ() 50 / 79 The smallpox data set has the following table proportions:

		inoculated		
		yes	no	Total
result	lived	0.038	0.825	0.863
	died	0.001	0.136	0.137
	Total	0.039	0.961	1.000

Let's find the probability that an inoculated person died from smallpox.

Find the probability that an inoculated person died from smallpox.

- We are told that the person is inoculated. This is our condition.
- We want to know the probability that this person died.
- This is the probability that a person died given that they were inoculated

 $P(\texttt{died} \mid \texttt{inoculated})$

Find the probability that an inoculated person died from smallpox.

		inoculated		
		yes	no	Total
result	lived	0.038	0.825	0.863
	died	0.001	0.136	0.137
	Total	0.039	0.961	1.000

$$P(\texttt{died} \mid \texttt{inoculated}) = \frac{P(\texttt{died} \text{ and } \texttt{inoculated})}{P(\texttt{inoculated})}$$
$$= \frac{0.001}{0.039} = 0.026$$

In the previous section, we talked about the multiplication rule for independent events. The **general multiplication rule** is for all events, whether or not they are independent.

Let A and B be any two outcomes or events. Then

$$P(A \text{ and } B) = P(A|B) \times P(B)$$

Notice that this is not new information! This is just a rearrangement of the formula for conditional probability.

San

<ロト (四) (三) (三) (三) (三)

Let's return to the smallpox data set, but suppose we only have two pieces of information:

- 96.08% of people were not inoculated.
- **2** 85.88% of people who were not inoculated ended up surviving.

Can we compute the probability that a resident was not inoculated and lived?

Compute the probability that a resident was not inoculated and lived.

First, let's rewrite the information we were given in probability notation.

- 96.08% of people were not inoculated
 → P(inoculated = no) = 0.9608
- 85.88% of people who were not inoculated ended up surviving $\rightarrow P(\texttt{result} = \texttt{lived} \mid \texttt{inoculated} = \texttt{no}) = 0.8588$

Compute the probability that a resident was not inoculated and lived.

Then we use this information with the general multiplication rule.

P(result = lived and inoculated = no)

- $= P(\texttt{result} = \texttt{lived} \ | \ \texttt{inoculated} = \texttt{no}) \times P(\texttt{inoculated} = \texttt{no})$
- $= 0.9608 \times 08588$

= 0.8251.

Let A_1, \ldots, A_k represent all the disjoint outcomes for a variable or process. Then if B is some event,

$$P(A_1|B) + \dots + P(A_k|B) = 1$$

The rule for complements also holds when an event and its complement are conditioned on the same information:

$$P(A|B) = 1 - P(A^c|B)$$

Why are these true? Let's look at a Venn diagram.

For two independent events, knowing the outcome of one should give us no information about the probability of the other. Consider X and Y, the outcomes for rolling two six-sided dice.

• Find
$$P(X = 1)$$
.

2 Find
$$P(X = 1 \text{ and } Y = 1)$$
.

• Find
$$P(Y = 1 | X = 1)$$
.

Knowing the outcome of X doesn't give us any additional information about Y.

San

<ロト (四) (三) (三) (三) (三)

We can use the Multiplication Rule to show that the conditioning information has no influence for independent processes:

$$P(Y = 1 | X = 1) = \frac{P(Y = 1 \text{ and } X = 1)}{P(X = 1)}$$
$$= \frac{P(Y = 1)P(X = 1)}{P(X = 1)}$$
$$= P(Y = 1)$$

San

A roulette wheel has 18 black slots, 18 red slots, and 2 green slots (38 total slots).

Ron is watching a roulette table in a casino and notices that the last five outcomes were **black**. He figures that the chances of getting **black** six times in a row is very small (about 1/64) and puts his paycheck on red.

What is wrong with his reasoning?

5900

<ロト (四) (三) (三) (三) (三)

What is wrong with Ron's reasoning?

- It's true that there is close to a 1/64 = 0.016 chance that we get black six times in a row.
 - $P(\texttt{black}_1) \times \cdots \times P(\texttt{black}_5) \times P(\texttt{black}_6) = (9/19)^6 = 0.011$
- But there's also a 1/64 chance that we get **black** five times in a row followed by **red**.
 - $P(\texttt{black}_1) \times \cdots \times P(\texttt{black}_5) \times P(\texttt{red}_6) = (9/19)^6 = 0.011$

What is wrong with Ron's reasoning?

- Each spin is independent of the previous spins!
- This means that each spin has a 18/38 chance of being black!
- Ron has a $1 \frac{18}{38} = 0.538$ chance of losing his entire paycheck.

Tree diagrams help organize outcomes and probabilities based on the structure of the data. They are especially useful when the data can be put into some kind of sequential structure.

- The smallpox data can be structured this way.
- We split the data by inoculation (yes or no).
- Then we split by result (lived or died).

- The first branch, for inoculation, is called the primary branch.
- All other branches, in this case for result are secondary branches.

67 / 79

- A E M

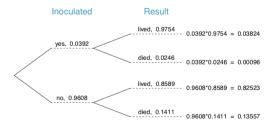

Image: A matrix

프 🕨 🗉 프

- The probabilities for the primary branch are marginal.
 - For inoculation is yes, the marginal probability is P(inoculation is yes) = 0.0392.
- The probabilities for the secondary branches are conditional.
 - For result is lived on the inoculation is yes branch, we have $P(\text{result is lived} \mid \text{inoculation is yes}) = 0.9754$

イロト イヨト イヨト イヨト

- Joint probabilities are shown to the right of each secondary branch.
- These are computed using the General Multiplication Rule

$$P(A \text{ and } B) = P(A|B) \times P(B)$$

where the primary branch represents event B and the secondary branch event A.

포 - 프

Consider the midterm and final for a statistics class.

- Suppose 13% of students earned an A on the midterm.
- Of those students who earned an A on the midterm, 47% received an A on the final.
- 11% of the students who earned lower than an A on the midterm received an A on the final.
- You pick up a final exam at random and notice the student received an A.

What is the probability that this student earned an A on the midterm?

- -

San

Let's start by writing the given information in probability notation.

•
$$P(\text{midterm} = A) = 0.13$$

- $P(\texttt{final} = \texttt{A} \mid \texttt{midterm} = \texttt{A}) = 0.47$
- $P(\texttt{final} = \texttt{A} \mid \texttt{midterm} = \texttt{not} \mid \texttt{A}) = 0.11$

We want to know the probability that a student who earned an A on the final also earned an A on the midterm:

$$P(\texttt{midterm} = \texttt{A} \mid \texttt{final} = \texttt{A})$$

4 ロ ト 4 回 ト 4 王 ト 4 王 ト 王 今 Q (* 71 / 79

Now that we've formalized the information from the problem statement, we can consider our next steps.

It's not yet clear how to calculate

$$P(\texttt{midterm} = A \mid \texttt{final} = A),$$

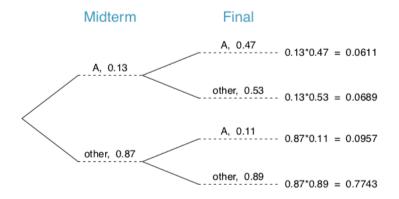

so let's use what we know to draw a tree diagram.

We will use this information to draw our tree diagram.

•
$$P(\texttt{midterm} = \texttt{A}) = 0.13$$

•
$$P(\texttt{final} = \texttt{A} \mid \texttt{midterm} = \texttt{A}) = 0.47$$

• $P(\texttt{final} = \texttt{A} \mid \texttt{midterm} = \texttt{not} \mid \texttt{A}) = 0.11$

Can we use this to calculate $P(\text{midterm} = A \mid \text{final} = A)$?

S	ec	tion	3.2

74 / 79

문▶ 문

5900

・ロト ・回ト ・ヨト ・

First, consider our conditional probability formula.

$$P(\texttt{midterm} = \texttt{A} \ | \ \texttt{final} = \texttt{A}) = \frac{P(\texttt{midterm} = \texttt{A} \ \texttt{and} \ \texttt{final} = \texttt{A})}{P(\texttt{final} = \texttt{A})}$$

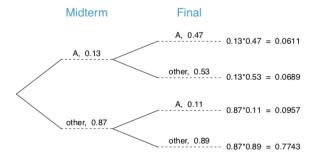

We can get all of the probabilities on the right hand side of the formula by using our tree diagram!

75 / 79

200

◆□ ▶ ◆□ ▶ ◆臣 ▶ ◆臣 ▶ ─ 臣 -

Example: Exam Scores

First,

P(midterm = A and final = A) = 0.0611.

76 / 79

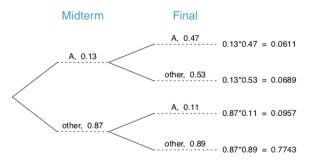

< E

æ

990

A B +
 A B +
 A

Example: Exam Scores

$$\begin{split} P(\texttt{final} = \texttt{A}) \\ &= P(\texttt{midterm} = \texttt{not A} \text{ and } \texttt{final} = \texttt{A}) + P(\texttt{midterm} = \texttt{A} \text{ and } \texttt{final} = \texttt{A}) \\ &= 0.0957 + 0.0611 = 0.1568 \end{split}$$

77 / 79

æ

5900

< D > < D

Plugging these in,

$$\begin{split} P(\texttt{midterm} = \texttt{A} \ | \ \texttt{final} = \texttt{A}) &= \frac{P(\texttt{midterm} = \texttt{A} \text{ and } \texttt{final} = \texttt{A})}{P(\texttt{ final} = \texttt{A})} \\ &= \frac{0.0611}{0.1568} = 0.3897. \end{split}$$

So the probability that a student earned an A on the midterm, given that their final exam score was an A, is about 39%.

That was a lot of work!

Bayes' Theorem will help minimize this work so that we can more easily calculate

P(statement about variable 1 | statement about variable 2)

when we have information about

P(statement about variable 2 | statement about variable 1).
