Key: 6 3 = 63 years old

- Suppose a health insurance company found that 70% of the people they insure stay below their deductible in any given year.
- Each of these people can be thought of as a single trial in a study.
- We label a person a "success" if their healthcare costs do not exceed the deductible.

•
$$P(\texttt{success}) = p = 0.7$$

•
$$P(\texttt{failure}) = 1 - p = 0.3$$

3

590

イロト 不得下 不同下 イヨト

- When an individual trial only has two possible outcomes it is called a Bernoulli random variable.
 - These outcomes are often labeled as success or failure.
- These labels can be completely arbitrary!
 - We called "not hitting the deductible" a "success", but we could just as well have labeled that the "failure".
 - The framework we use to talk about the Bernoulli distribution does not depend on the label we use.

Bernoulli random variables are often denoted as $1\ {\rm for}\ {\rm a}\ {\rm success}\ {\rm and}\ 0$ for a failure.

This makes data entry easy and is mathematically convenient.

Suppose we observe ten trials:

The **sample proportion**, \hat{p} , will be the sample mean for these observations:

$$\hat{p} = \frac{\# \text{ of successes}}{\# \text{ of trials}}$$
$$= \frac{1+1+1+0+1+0+0+1+1+0}{10}$$
$$= 0.6$$

- It is useful to think about a Bernoulli random variable as a random process with only two outcomes: a success or failure (or yes/no).
- Then we code a success as 1 and a failure as 0.
- These are just numbers, so we can define the mean and variance.

・ロト ・回ト ・ヨト ・

EN E SOO

If X is a random variable that takes the value 1 with probability of success p and 0 with probability 1 - p, then X is a **Bernoulli random variable** with mean

$$\mu = p$$

and variance

$$\sigma^2 = p(1-p).$$

Section 4.2.1

August 14, 2019

4 ロ ト 4 回 ト 4 三 ト 4 三 ト 三 の Q () 8 / 60

- Remember that we can estimate p using $\hat{p} = \bar{x}$.
- We can use this to estimate the mean the variance.
- For our insurance deductible example, we found $\hat{p} = 0.6$
- So we can estimate

$$\hat{\mu} = \hat{p} = 0.6$$

and

$$\hat{\sigma^2} = \hat{p}(1-\hat{p}) = 0.6 * 0.4 = 0.24$$

Derive the mean and variance of a Bernoulli random variable.

Section 4.2.1

August 14, 2019

Because there are only 2 possible outcomes, the Bernoulli distribution describes a *discrete random variable*.

Therefore, We can start with its probability distribution table:

x	0	1
P(x)	p	(1-p)

Then for the expected value,

x	1	0	Total
P(x)	p	(1 - p)	
xP(x)	p	0	p

So the expected value is (as expected) p!

And for the variance,

x	1	0	Total
P(x)	p	(1 - p)	
xP(x)	p	0	p
x - E(x)	1-p	-p	
$[x - E(x)]^2$	$(1-p)^2$	p^2	
$P(x)[x - E(x)]^2$	$p(1-p)^2$	$(1-p)p^2$	$p(1-p)^2 + (1-p)p^2$

August 14, 2019

13 / 60

5990

《曰》 《圖》 《臣》 《臣》 三臣。

Then

$$Var(X) = p(1-p)^{2} + (1-p)p^{2}$$

= $p - 2p^{2} + p^{3} + p^{2} - p^{3}$
= $p - 2p^{2} + p^{2}$
= $p - p^{2}$
= $p(1-p)$

Which is the Var(X) we wanted!

990

《口》 《四》 《臣》 《臣》 三臣

The **binomial distribution** is used to describe the number of successes in a fixed number of trials.

- This is an extension of the Bernoulli distribution.
- We check for a success or failure repeatedly over multiple trials.
- Each *individual* trial can be described with a Bernoulli distribution.

-

San

(日) (四) (日) (日)

- Let's return to the insurance agency where 70% of individuals do not exceed their deductible.
- Suppose the insurance agency is considering a random sample of four individuals they insure.
- What is the probability that exactly one of them will exceed the deductible and the other three will not?

-

Sar

イロト イボト イヨト イヨト

Let's call the four people Ariana (A), Brittany (B), Carlton (C), and Damian (D). Consider a scenario where one person exceeds the deductible:

$$\begin{split} P(A = \texttt{exceed}, B = \texttt{not}, C = \texttt{not}, D = \texttt{not}) \\ &= P(A = \texttt{exceed}) \times P(B = \texttt{not}) \times P(C = \texttt{not}) \times P(D = \texttt{not}) \\ &= (0.3) \times (0.7) \times (0.7) \times (0.7) \\ &= (0.3)^1 \times (0.7)^3 \\ &= 0.103 \end{split}$$

- But there are three other scenarios!
 - **1** Brittany could have been the one to exceed the deductible.
 - **2** ... or Carlton could have.
 - I ... or Damian.
- In each of these cases, the probability is $(0.7)^3(0.3)^1$.

3

DQC

イロト イヨト イヨト イヨト

- These four scenarios consist of all the possible ways that exactly one of these four people could have exceeded the deductible.
- So the total probability is

$$4 \times (0.7)^3 \times (0.3)^1 = 0.412.$$

This is an example of a scenario where we would use a binomial distribution.

イロト イヨト イヨト イヨト

3

San

We would like to determine the probabilities associated with the binomial distribution using n, k, and p.

We would like a nice formula for this.

Let's return to our insurance example.

- There were four people who could have been the single failure.
- Each scenario has the same probability.
- So the final probability was

 $[\# \text{ of scenarios}] \times P(\text{single scenario})$

Sac

<ロト (四) (三) (三) (三) (三)

- The first component of this equation is the number of ways to arrange k = 3 successes among n = 4 trials.
- The second is the probability of any one of the scenarios.
 - These four scenarios are equally probable.

200

- Consider P(single scenario) with k successes and n k failures in n trials.
- We know how to handle this!
- We will use the multiplication rule for independent events.

Applying the multiplication rule for independent events,

$$P(\text{single scenario}) = P(k \text{ successes}) \times P(n-k \text{ failures})$$
$$= p \times \dots \times p \times (1-p) \times \dots \times (1-p)$$
$$= p^k \times (1-p)^{n-k}$$

This is our general formula for P(single scenario).

The number of ways to arrange k successes and n - k failures is

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}$$

The expression $\binom{n}{k}$ is read "n choose k". This is the number of ways to choose k successes in n trials.

What about the exclamation point?

The exclamation point in n! denotes a **factorial**.

0! = 1 1! = 1 $2! = 2 \times 1$ $3! = 3 \times 2 \times 1$ $4! = 4 \times 3 \times 2 \times 1$ \vdots $n! = n \times (n - 1) \times (n - 2) \times \dots \times 3 \times 2 \times 1$

Section 4.3

August 14, 2019

We can use this to double check our insurance deductible problem.

Recall that we decided that there were four possible ways to get 3 successes (not exceeding) among 4 people (trials).

$$\binom{4}{3} = \frac{4!}{3!(4-3)!}$$
$$= \frac{4 \times 3 \times 2 \times 1}{(3 \times 2 \times 1) \times (1)}$$
$$= 4$$

which is just what we decided before!

Suppose $X \sim Bin(n, p)$. The probability of a single trial being a success is p. Then the probability of observing exactly k successes in n independent trials is given by

$$P(X = k) = \binom{n}{k} p^k (1-p)^{n-k}$$

Section 4.3

August 14, 2019

The expected value (mean) is

$$E(X) = \mu = np$$

and the variance is

$$Var(X) = \sigma^2 = np(1-p)$$

If $p \approx (1-p)$, then the binomial distribution is symmetric.

We say that X follows a **binomial distribution** with number of trials n and probability of success p if

- The number of trials is fixed = n.
- **2** The trials are independent.
- There are two possible outcomes, success/failure.
- **(**) The probability of success is known and fixed = p.

We denote this $X \sim \operatorname{Bin}(n, p)$

Normal Approximation to the Binomial Distribution

- Sometimes when *n* is large, the binomial formula can be difficult to use.
- In these cases, we may be able to use the normal distribution to estimate binomial probabilities.

イロト イヨト イヨト ・

3

San

- Approximately 15% of the US population smokes cigarettes.
- A local government commissioned a survey of 400 randomly selected individuals.
- The survey found that only 42 of the 400 participants smoke cigarettes.
- If the true proportion of smokers in the community was really 15%, what is the probability of observing 42 or fewer smokers in a sample of 400 people?

San

<ロト (四) (三) (三) (三) (三)

First, we check that this is a binomial setting:

- n = 400 community members
- **2** This is a random sample, so the trials are independent.
- **③** We define Success = smoker and Failure = nonsmoker.

$$\textcircled{9} \ p = P(\texttt{smoker}) = 0.15$$

So this is a binomial distribution.

We are interested in k = 42 or fewer.

Let X be the number of smokers in a community. We want to know

$$P(X \le 42)$$

which is the same as

$$P(X = 42 \text{ or } X = 41 \text{ or } X = 40 \text{ or } \dots \text{ or } X = 1 \text{ or } X = 0)$$

= $P(X = 42) + P(X = 41) + \dots + P(X = 1) + P(X = 0)$

We *could* calculate each of the 43 probabilities individually by using our binomial formula and adding them together...

If we were to do this, we would find

$$P(X = 42) + P(X = 41) + \dots + P(X = 1) + P(X = 0) = 0.0054$$

That is, if the true proportion of smokers in the community is p = 0.15, then the probability of observing 42 or fewer smokers in a sample of n = 400 is 0.0054. ...but why would we do this if we don't have to?

- Calculating probabilities for a range of values is much easier using the normal model.
- We'd like to use the normal model in place of the binomial distribution.

San

Surprisingly, this works quite well as long as

np > 10

and

$$n(1-p) > 10$$

Note that both of these conditions must hold!

DQC

(日) (四) (전) (전) (전) (전)

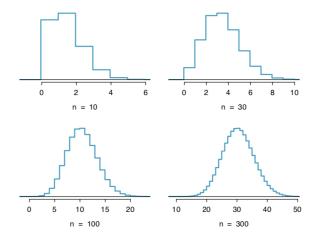

If these conditions are met, then $X\sim \mathrm{Bin}(n,p)$ is well-approximated by a normal model with

$$E(X) = \mu = np$$

and

$$Var(X) = \sigma^2 = np(1-p).$$

Normal Approximation to the Binomial Distribution

Each histogram shows a binomial distribution with p = 0.1.

Can we use the normal approximation to estimate the probability of observing 42 or fewer smokers in a sample of 400, if the true proportion of smokers is p = 0.15?

Can we use the normal approximation to estimate the probability of observing 42 or fewer smokers in a sample of 400, if the true proportion of smokers is p = 0.15?

From our previous example, we verified that the binomial model is reasonable. Now,

$$np = 400 \times 0.15 = 60$$

and

$$n(1-p) = 400 \times 0.85 = 340$$

so both are at least 10 and we may use the normal approximation.

For the normal approximation,

$$\mu = np = 400 \times 0.15 = 60$$

and

$$\sigma = \sqrt{np(1-p)} = \sqrt{400 \times 0.15 \times 0.85} = 7.14$$

August 14, 2019

<□▶ <□▶ < 三▶ < 三▶ < 三▶ E のへで 50 / 60 We want to find the probability of observing 42 or fewer smokers using or $N(\mu = 60, \sigma = 7.14)$ model.

We start by finding our Z-score:

$$z = \frac{x - \mu}{\sigma} = \frac{42 - 60}{7.14} = -2.52$$

August 14, 2019

- Then, using R, the left-tail area is 0.0059.
- When we calculated this using the binomial distribution, the true probability was 0.0054.
- So this is a pretty good approximation!

(日) (종) (종) (종)

3

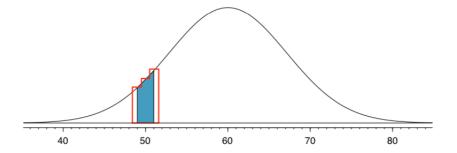

590

- The normal approximation to the binomial distribution tends to perform poorly when estimating the probability of a small range of counts.
- This is true even when np > 10 and n(1-p) > 10

- Suppose we wanted to compute the probability of observing 49, 50, or 51 smokers in 400 when p = 0.15.
- We know that np = 60 > 10 and n(1-p) = 340, so we might want to apply the normal approximation and use the range 49 to 51.
- But this time the approximation and the binomial solution are noticeably different!
 - Binomial: 0.0649
