A D > A D >

토 🛌 🗄

In this section, we will talk about fitting a line to data.

- Linear regression will allow us to look at relationships between two (or more) variables.
- This is a bit like ANOVA, but now we will be able to *predict* outcomes.

프 🕨 🛛 프

DQC

Fitting a Line to Data

This relationship can be modeled perfectly with a straight line:

$$y = 5 + 64.96x$$

I.e., x and y are perfectly correlated.

Section 8.1

When we can model a relationship *perfectly*,

y = 5 + 64.96x,

we know the exact value of y just by knowing the value of x.

However, this kind of perfect relationship is pretty unrealistic... it's also pretty uninteresting.

Linear regression takes this idea of fitting a line and allows for some error:

$$y = \beta_0 + \beta_1 x + \epsilon$$

- β_0 and β_1 are the model's parameters.
- The error is represented by ϵ .

- \bullet The parameters β_0 and β_1 are estimated using data.
- We denote these point estimates by b_0 and b_1 .
 - ... or sometimes $\hat{\beta}_0$ and $\hat{\beta}_1$

・ロト ・回ト ・ヨト

三 三 つくつ

For a regression line

$$y = \beta_0 + \beta_1 x + \epsilon$$

we make predictions about y using values of x.

- y is called the **response variable**.
- x is called the **predictor variable**.

< D > < B >

포 표

When we find our point estimates b_0 and b_1 , we usually write the line as

$$\hat{y} = b_0 + b_1 x$$

We drop the error term because it is a random, unknown quantity. Instead we focus on \hat{y} , the predicted value for y.

As with any line, the intercept and slope are meaningful.

- The slope β_1 is the change in y for every one-unit change in x.
- The intercept β_0 is the predicted value for y when x = 0.

10 / 36

< D > < D

≣ ► = =

Think of this like the 2-dimensional version of a point estimate.

- The line gives our best estimate of the relationship.
- There is some variability in the data that will impact our confidence in our estimates.
- The true relationship is unknown.

3

<ロト <回ト < 回ト < 三ト

Linear Trends

Sometimes, there is a clear relationship but simple linear regression won't work! We will talk about this later in the term.

Often, when we build a regression model our goal is prediction.

• We want to use information about the predictor variable to make predictions about the response variable.

Example: Possum Head Lengths

Remember our brushtail possums?

Section 8.1

October 28, 2019

14 / 36

E> E

DQC

A D > A D >

Researchers captured 104 brushtail possums and took a variety of body measurements on each before releasing them back into the wild.

We consider two measurements for each possum:

- total body length.
- head length.

Example: Possum Head Lengths

16 / 36

< A

æ

- The relationship isn't perfectly linear.
- However, there does appear to be a linear relationship.
- We want to try to use body length to predict head length.

200

<ロト (四) (三) (三) (三) (三)

The textbook gives the following linear relationship:

 $\hat{y} = 41 + 0.59x$

As always, the hat denotes an estimate of some unknown true value.

Example: Possum Head Lengths

Predict the head length for a possum with a body length of 80 cm.

19 / 36

If we had more information (other variables), we could probably get a better estimate.

We might be interested in including

- sex
- region
- diet

or others.

Absent addition information, our prediction is a reasonable estimate.

Residuals are the leftover variation in the data after accounting for model fit:

data = prediction + residual

Each observation will have its own residual.

Formally, we define the residual of the *i*th observation (x_i, y_i) as the difference between observed (y_i) and expected (\hat{y}_i) :

$$e_i = y_i - \hat{y}_i$$

We denote the residuals by e_i and find \hat{y} by plugging in x_i .

If an observation lands above the regression line,

$$e_i = y_i - \hat{y}_i > 0.$$

If below,

$$e_i = y_i - \hat{y}_i < 0.$$

臣

590

(日) (四) (日) (日) (日)

When we estimate the parameters for the regression, our goal is to get each residual as close to 0 as possible.

Example: Possum Head Lengths

The residual for each observation is the vertical distance between the line and the observation.

25 / 36

The scatterplot is nice, but a calculation is always more precise. Let's find the residual for the observation (77.0, 85.3).

(日) (종) (종) (종)

3

- Our goal is to get our residuals as close as possible to 0.
- Residuals are a good way to examine how well a linear model fits a data set.
- We can examine these quickly using a residual plot.

・ロト ・回ト ・ヨト

3

Sac

Residual plots show the x-values plotted against their residuals.

28 / 36

- We use residual plots to identify characteristics or patterns.
- These are things that are still apparent event after fitting the model.
- Obvious patterns suggest some problems with our model fit.

문 🛌 🗄

We've talked about the strength of linear relationships, but it would be nice to formalize this concept.

The **correlation** between two variables describes the strength of their linear relationship. It always takes values between -1 and 1.

DQC

《日》 《圖》 《문》 《문》 [] 문)

We denote the correlation (or correlation coefficient) by R:

$$R = \frac{1}{n-1} \sum_{i=1}^{n} \left(\frac{x_i - \bar{x}}{s_x} \times \frac{y_i - \bar{y}}{s_y} \right)$$

where s_x and s_y are the respective standard deviations for x and y.

Correlations

- Close to -1 suggest strong, negative linear relationships.
- Close to +1 suggest strong, positive linear relationships.
- Close to 0 have little-to-no linear relationship.

 $\equiv \rightarrow$

・ロト ・回ト ・ヨト

3

Note: the sign of the correlation will match the sign of the slope!

- If R < 0, there is a downward trend and $b_1 < 0$.
- If R > 0, there is an upward trend and $b_1 > 0$.
- If $R \approx 0$, there is no relationship and $b_1 \approx 0$.
